BACKGROUND OF THE INVENTIONField of the Invention

- This invention relates to plasma processing of semiconductor devices. In
particular, this invention provides a method and apparatus to calibrate a semi-
20 empirical process simulator for predicting the surface profile and the etch or
deposition rates that a given plasma process will create.

Background Art

Various forms of processing with ionized gases, such as plasma etching and reactive ion etching, are increasing in importance particularly in the area of semiconductor device manufacturing. Of particular interest are the devices used in the etching process. FIG. 1A illustrates a conventional inductively coupled plasma etching system 100 that may be used in the processing and fabrication of semiconductor devices. Inductively coupled plasma processing system 100 includes a plasma reactor 102 having a plasma chamber 104 therein. A transformer coupled power (TCP) controller 106 and a bias power controller 108 respectively control a TCP power supply 110 and a bias power supply 112 influencing the plasma created within plasma chamber 104.

TCP power controller 106 sets a set point for TCP power supply 110 configured to supply a radio frequency (RF) signal, tuned by a TCP match network 114, to a TCP coil 116 located near plasma chamber 104. A RF transparent window 118 is typically provided to separate TCP coil 116 from plasma chamber 104 while allowing energy to pass from TCP coil 116 to plasma chamber 104.

Bias power controller 108 sets a set point for bias power supply 112 configured to supply a RF signal, tuned by a bias match network 120, to an electrode 122 located within the plasma reactor 104 creating a direct current (DC) bias above electrode 122 which is adapted to receive a substrate 124, such as a semi-conductor wafer, being processed.

A gas supply mechanism 126, such as a pendulum control valve, typically supplies the proper chemistry required for the manufacturing process to the interior of plasma reactor 104. A gas exhaust mechanism 128 removes particles from within plasma chamber 104 and maintains a particular pressure within plasma chamber 104. A pressure controller 130 controls both gas supply mechanism 126 and gas exhaust mechanism 128.

A temperature controller 134 controls the temperature of plasma chamber 104 to a selected temperature setpoint using heaters 136, such as heating cartridges, around plasma chamber 104.

In plasma chamber 104, substrate etching is achieved by exposing substrate 104 to ionized gas compounds (plasma) under vacuum. The etching process starts when the gases are conveyed into plasma chamber 104. The RF power delivered by TCP coil 116 and tuned by TCP match network 110 ionizes the gases. The RF power, delivered by electrode 122 and tuned by bias match network 120, induces a DC bias on substrate 124 to control the direction and energy of ion bombardment of substrate 124. During the etching process, the plasma reacts chemically with the surface of substrate 124 to remove material not covered by a photoresistive mask.

Input parameters such as plasma reactor settings are of fundamental importance in plasma processing. The amount of actual TCP power, bias power, gas pressure, gas temperature, and gas flow within plasma chamber 104 greatly affects the process conditions. Significant variance in actual power delivered to plasma chamber 104 may unexpectedly change the anticipated value of other

process variable parameters such as neutral and ionized particle density, temperature, and etch rate.

Traditionally, a suite of values of these input parameters suitable for creating a given set of device features has been determined by trial and error.

5 Development of a single process by this empirical approach is costly and time-consuming, requiring treatment of several patterned wafers and subsequent study of the resulting profiles by scanning electron microscopy. Because of the unpredictable way a small change in one input parameter may affect the profile, any modification of the layout--for example, in device dimension, pattern density
10 on the wafer or change in total open area--from one application to another, has often necessitated redevelopment of the process, with the attendant outlay of resources.

Recent advances in device fabrication technology are rendering this approach even more onerous. Decreasing feature sizes demand tighter tolerances
15 on feature dimensions and morphologies, so that the number of trials required to optimize a given process is increasing. The acceleration of wafer diameter growth and the complete redesign of the process involved with an incremental change in diameter have increased the number of times this empirical process must be repeated. The increasing use of devices tailor-made to a specific application also
20 increases the amount of development and optimization activity required.

An alternative, computational approach would derive input parameters from a complete physical description of a plasma process including a plasma

model for describing the coupling between the macroscopic input parameters and the macroscopic fluxes, concentrations and energy distributions of the various species in the plasma; and a profile simulator for determining atomistically from the macroscopic fluxes the resulting etch or deposition rate along the wafer surface and calculating the profile evolution therefrom. Ideally, such a physical description of plasma etching and deposition processes would enable the *ab initio* selection of the macroscopic input parameters appropriate for generating a desired profile on the substrate, eliminating the need for expensive and time-consuming test sequences.

Research in this field has done much to elucidate mechanisms at work in plasma processes, and thus has contributed scaling laws that could frame a physical description. However, notwithstanding the availability of computational means sufficiently powerful to perform the necessary calculations based on known scaling laws, the implementation of such an *ab initio* approach has been limited by lack of data. For example, the manner in which the values of some coefficients in these laws depend on the particulars of a given process is unknown as yet. In some investigations, determination of the value of such a scaling coefficient consistent with a plasma process defined by a given set of input parameters has been done by comparing a finished profile, created by applying that process, with a simulated profile including one or more of these coefficients as adjustable parameters. Such hindsight evaluation may promote understanding a given coefficient's role in scaling law, but it has not afforded the ability to predict profile

evolution for any process defined by a set of input parameters differing from the set used in the experimental process used to derive the value of that coefficient.

Thus, there is a need for a method for calibrating a semi-empirical process simulator for predicting the surface profiles and the etch or deposition rates that a given plasma process will create.

5

SUMMARY OF THE INVENTION

A method and apparatus for calibrating a semi-empirical process simulator used to determine process values in a plasma process for creating a desired surface profile on a process substrate includes providing a test model which captures all mechanisms responsible for profile evolution in terms of a set of unknown surface parameters. A set of test conditions is derived for which the profile evolution is governed by only a limited number of parameters. For each set of test conditions, test values are selected and a test substrate is actually subjected to a test process defined by the test values, thereby creating a test surface profile. The test values are used to generate an approximate profile prediction and are adjusted to minimize the discrepancy between the test surface profile and the approximate profile prediction, thereby providing a final model of the profile evolution in terms of the process values.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A is a block diagram illustrating a plasma etching system.

- 5 FIG.1B is a flow chart illustrating a first calibration process in accordance with a specific embodiment of the present invention.

FIG. 2 is a flow chart illustrating a second calibration process in accordance with a specific embodiment of the present invention.

10

FIG. 3 is an elevational cross-sectional diagram depicting surface kinetics in a plasma process according to the Langmuir model.

FIG. 4 is a system block diagram illustrating a representative hardware

- 15 environment in accordance with a specific embodiment of the present invention.

DETAILED DESCRIPTION OF A SPECIFIC EMBODIMENTS OF THE
INVENTION

Those of ordinary skill in the art will realize that the following description
5 of the present invention is illustrative only and not in any way limiting. Other
embodiments of the invention will readily suggest themselves to such skilled
persons having the benefit of this disclosure.

A semi-empirical process simulator is a model that seeks to determine the
10 values of input parameters in a plasma process for creating a desired surface
profile on a substrate, such as a semi-conducting wafer. Previous calibration
schemes used in the process simulator relied on fitting the simulation output to test
data gathered near a process window of interest. While useful, this technique is
likely to produce more empirical and less physically based models. An alternative
15 approach to calibration is to design sets of experiments in which the results are
functions of fewer unknown parameters and for which coefficient values can be
derived from best fit to data with greater confidence. The present invention seeks
to improve such calibration process by using models that more faithfully capture
the actual kinetics governing feature evolution and are likely to yield more
20 accurate profile predictions when using reactor settings which may lie outside a
previously calibrated window of operation.

The form of the surface kinetic model for each class of exposed film and class of plasma chemistry may be derived from experimentally observed trends and scalings. Unknown model coefficients however must be calibrated for each specific film and chemistry. A complete surface kinetics model includes equations governing surface coverage and an equation governing etch or deposition rate. Surface reaction rates for the adsorption, desorption, and surface reactions of active neutral species lead to a determination of surface coverage. The mechanisms determining local etch rate will be functions of the computed surface coverage and the ion and neutral flux distributions incident on a feature surface element. Etch mechanisms include physical sputtering due to energetic particle bombardment, chemical assisted sputtering which additionally depends on the surface concentration of one or more etchant species, and thermal etching dependent only on chemical coverages (and surface temperature). Deposition rate is typically defined by the adsorption rate of depositing neutral species.

The general procedure to calibrate a semi-empirical process simulator is illustrated in FIG. 1. Free parameters needed to characterize mechanisms such as thermal etching, ion enhanced etching, physical sputtering, and deposition are determined by performing test processes under conditions where only a limited number of such mechanisms contribute to etch or deposition rates and/or surface profiles. The reduced set of unknown surface parameters can then be determined by best fit to etch rate and/or surface profile data collected under these conditions.

In block 100, a test model which captures all mechanisms responsible for profile evolution in terms of a set of unknown surface parameters is provided. The input parameters include descriptors of the pre-processing state of the substrate ("substrate parameters") and quantities defining the operation of a given plasma reactor during the test process ("reactor parameters"). The substrate parameters may include, for example, gross dimensions of the substrate, the distribution and dimensions of any features on the surface, and the substrate composition. The reactor parameters may include any of: power levels, gas temperature, gas pressure, inlet gas composition, and length of time the substrate is treated by the plasma process.

In block 102, a set of test conditions is derived from a subset of the test model defined in block 100 such that only a limited number of unknown surface parameters contribute to the etch or deposition rates and the surface profiles. Such test conditions is derived by adjusting the value of some of the surface parameters to render their effects negligible on the test processes.

For each set of test conditions defined in block 102, surface model unknown parameter test values are yet to be solved for. In block 104, these unknown parameter test values are isolated by eliminating parameters that do not contribute to etch or deposition rates or feature evolution.

The unknown parameter test values of reactor variables and reactor fixed parameters as selected in block 106, are used in block 108, in which a plasma model, containing a mathematical description of the plasma in terms of the reactor parameters for the reactor of interest and coefficients of known or empirically determined value, operates to approximately determine the macroscopic properties of the plasma generated by the test process. The plasma model characterizes the species of interest only as belonging to a general class of actors, for example, as being either charged particles, and thus attracted to the substrate by any applied bias, or neutral species such as gas molecule and excited radicals. Physical models--for example, Maxwell's and Boltzmann's equations--underlying the functional dependence in terms of governing experimental input parameters of such plasma descriptors as particle fluxes, energy, and angular distributions are well known in the art. (See, e.g., Lieberman and Lichtenberg, *Principles of Plasma Discharges and Materials Processing*, JohnWiley, 1994). Much is known in the art about how these descriptors scale with the input parameters, based on such basic physical models in conjunction with experimental data. However, the absolute value of these fluxes or distributions is not known *a priori* for a given process. Any such coefficient in the reactor model whose value is unknown is treated by the calibration as an adjustable parameter or is determined experimentally.

Those macroscopic properties of the plasma can alternatively be determined by measuring the flux distribution at the wafer in a laboratory under the set of test conditions as selected in block 104.

5 In block 112, a profile simulator, containing a mathematical model of the time evolution of the substrate surface profile in terms of the substrate parameters, the macroscopic plasma properties, and coefficients of unknown value, uses the results of block 108 and the substrate parameters provided in block 110 to approximately predict the etch or deposition rates and surface profiles on the
10 substrate. In general, such mathematical model includes a local transport model for calculating fluxes arriving at each point along the substrate surface, a site balance model for calculating the resulting local etch and deposition rates, and a surface advancement algorithm. In a presently preferred specific embodiment of the present invention, a well-known Monte Carlo type approach is used for the
15 local transport.

The site balance model is preferably based on a Langmuir-type model of the kinetics of particle-surface interactions. The model characterizes species that remove material from the substrate as etchants and those that deposit material onto the substrate surface as inhibitors. With reference to FIG. 3, Γ_e and Γ_d respectively
20 represent fluxes of etchants and inhibitors arriving at the surface of the substrate 300. Both etchants and inhibitors react with the surface when they encounter a vacant site. Etchant and inhibitor species react at the surface with respective open-

field reaction coefficients of S_e and S_d to form etchant site 302 and inhibitor site 304. The overall occupancies of the substrate surface sites resulting from reactions with etchant and inhibitor species are represented respectively by fractions θ_e and θ_d , with the number of vacant sites 306 being equal to $1-\theta_e-\theta_d$.

- 5 Etch products can form and thermally desorb from the surface. Ions arriving at the surface, at flux Γ , can remove etchants that have reacted with the surface by physical sputtering and ion-enhanced etching; arriving ions can also remove inhibitors from the surface by physical sputtering. Taking into account these assumptions and mechanisms, the site balance, in the steady state, for the two
- 10 types of occupied sites be expressed respectively as

$$\sigma_e d\theta_e/dt = \Gamma_e S_e (1-\theta_d-\theta_e) - \theta_e k_{sl} \Gamma_{ie} - \theta_e k_{el} \Gamma_{ie} k_{th,e} \theta_e \cong 0 \text{ and}$$

$$\sigma_d d\theta_d/dt = \Gamma_d S_d (1-\theta_d-\theta_e) - \theta_d k_{sl} \Gamma_{ie} \cong 0,$$

- 15 Wherein k_{el} , k_{sl} , and k_{th} are coefficients, generally of unknown value, associated with the ion-enhanced, physical sputtering and thermal etching mechanisms, respectively. The parameters Γ_{ie} and Γ_{is} are products of ion-enhanced etching and physical sputtering yields, respectively, with ion flux integrated over incident ion energies greater than respective threshold energies, expressed respectively as E_{th}
- 20 and E_{th} , and over all angles,

$$\Gamma_{ie} = \iint Y_{ie}(\phi, E) \Gamma_1(\phi, E) d\phi dE = \int dE (E^{\frac{1}{2}} - E_{th,e}^{\frac{1}{2}}) \int d\phi Y_e(\phi, E) \int_1(\phi, E) \text{ and}$$

$$\Gamma_{is} = \iint Y_{is}(\phi, E) \Gamma_1(\phi, E) d\phi dE = \int dE (E^{\frac{1}{2}} - E_{th,s}^{\frac{1}{2}}) \int d\phi Y_s(\phi, E) \int_1(\phi, E) .$$

This model assumes that the etch yields are products of angular functions and the square root of ion energy, which dependence has been observed experimentally. However, other scaling laws could be used instead. The yield functions only represent functional dependencies, the absolute magnitudes being
 5 lumped into the coefficients k 's along with other constants.

Expressions for θ_e and θ_d can be derived from the steady-state site balance equation on each type of surface present on the substrate, for example the substrate top and trench bottoms and sidewalls. At each point on the surface, the etch rate,
 10 ER, can be written:

$$ER = k_{s2} \Gamma_{ls} + \theta_e k_{e2} \Gamma_{ie} + k_{th} \Gamma_e - k_d \Gamma_d S_d (1 - \theta_e).$$

The coefficients k_{e2} , k_{s2} , k_d and k_{th} are yield constants associated with physical sputtering, ion-enhanced etching, thermal etching and ion-induced deposition, respectively. Incorporating the expressions for θ_e , θ_d , Γ_{ls} and Γ_{ie} renders the etch
 15 rate in terms of the plasma characteristics and the coefficients k , each of which is in principle an adjustable parameter that can be determined by the calibration.

It is also preferred to employ an analytic scheme for surface advancement so that the fine features can be resolved more accurately. One such scheme known in the art and capable of modeling fine feature aspects, such as sharp corners, is
 20 the method of characteristics, also known as the shock-front-tracking algorithm. (See, e.g., S. Hamaguchi, "Modeling of Film Deposition for Microelectronic Applications", *Thin Films*, vol. 22, p. 81, S. Rossmagel, ed. Academic Press, San

Diego, 1996). Another is the level set approach. (See, e.g., J.A. Sethian, *Level Set Methods: Evolving Interfaces in Geometry, Fluid Mechanics, Computer Vision, and Materials Science*, Cambridge University Press 1996). The shock-front-tracking approach models the surface (i.e., the interface layer between vacuum and solid) as a collection of piecewise continuous line segments, for each of which a rate of movement is calculated. The possibility of each segment's advancing or receding along its normal independently of the movement of the other segments allows for multiple potential solutions for the resulting surface. In order to avoid multiple solutions, these analytic schemes model the points between the line segments as shocks (i.e., discontinuities in the slope), and properly track the movement of the shocks.

Thus, the cumulative output of blocks 104 through 112, particularly of the operation of the plasma model in block 108 and the profile simulator in block 112, which together comprise an initial mathematical surface profile model as specified above, generates a quantitative but approximate prediction of the etch or deposition rates and surface profile(s) created by the test process.

In block 114, the test values of the input parameters provided in block 104 are used to provide a test surface profile, created experimentally by subjecting a test substrate to a test process, in the reactor of interest, defined by the test values of the input parameters. The etch or deposition rates and surface profile(s) of the

test substrate are then measured. In block 116, the etch or deposition rates and surface profile(s) of the test substrate are quantitatively compared with the quantitative approximate prediction resulting from block 112. The difference between the test surface profile(s) and/or etch/deposition rates and the approximate prediction(s) is evaluated according to some criterion, such as an accuracy of range of 10%, applied in block 116.

In general, on the first pass, in which the approximate prediction(s) is computed using preliminary test values of unknown surface parameters, the residual is not sufficiently small to satisfy the criterion, and the calibration procedure advances to block 118, in which the values of the unknown surface parameters are adjusted so as to minimize the discrepancy. The adjusted values are then resubmitted to the profile simulator of block 112 and the plasma model of block 108, for another iteration that render the approximate profile prediction(s) and of the comparison in block 116. Iteration continues until the discrepancy between the test surface profile(s) and the approximate prediction(s) is adequately minimized.

Thus, both block 116 and block 118 effect a calculation of optimum values of the unknown surface parameters test values appearing in the initial mathematical surface profile model. After the surface parameters suitable for the current set of conditions are determined, a different set of conditions in block 104 is selected from block 102 and its respective surface parameters are determined

using the same process of block 104 through block 120 until all surface parameters are determined.

For example, physical sputtering yield, energy scaling, and energy threshold coefficients may be obtained by fitting to etch rate data and final profile SEM (Scanning Electron Micrograph) data collected after wafer processing in a chemically inert plasma such as an argon discharge with the ion flux and energy distribution to the separately measured or modeled. Coefficients representing thermal etch rate may be obtained by best fit to etch rate data collected under conditions for which there is no energetic ion bombardment. If sufficient gas phase reactant density can be achieved the surface will saturate and the dependence of etch rate on adsorption probability can be eliminated leaving saturated etch rate as the only unknown parameter. Patterned features including overhang structures may be etched in order to isolate surface reaction probabilities which determine transport throughout the feature. In order to calibrate models for deposited material, deposition and etch rates on blanket or patterned wafers processed under conditions favoring deposition may be collected. Incomplete film stacks may be used to isolate the mechanisms leading to redeposition. For chemically assisted sputtering, also referred to as ion-neutral synergy etching, data may be collected from wafers processed under conditions where the ratio of ion energy flux to etchant neutral flux is varied. For large (small) enough ion energy flux to etchant neutral flux ratios the etch rate is dependent only on the etchant flux (incident ion energy flux). Model fits to this etch rate and profile data combined with ion

and/or neutral flux measurements and/or models can be used to determine unknown coefficients including neutral sticking coefficient, neutral desorption and/or recombination rates, average etch product stoichiometry, and yield per incident ion as a function of energy and angle. For all the sets of experiments
5 above subsets of the complete process chemistry may be used to further isolate and calibrate specific reactions.

In one presently alternative specific embodiment, the approximate profile
10 prediction generated by the profile simulator in block 112 comprises a series of frames, each computed after a sufficiently small time increment, and block 114 only compares frames of the approximate profile prediction that correspond to cumulative exposure times roughly equal to the time of the snapshots in the test surface profile. If the test profile includes multiple snapshots at different exposure
15 times and/or at a different test value of one or more input parameters other than time, block 116 compares each test snapshot with the appropriate frame of the profile prediction and the system operates to minimize the residual over the entire pairwise comparison.

20 As will now be evident to those of ordinary skill in the art, many configurations departing from the procedure shown in FIG. 1 fall within the scope of the invention. For example, FIG. 2 illustrates another specific embodiment in which block 206 combines the plasma model with the unknown parameter test

values and the substrate parameters in a single module. The entire initial mathematical surface profile model may reside in a single module, block 206, rather than being divided into distinct parts 108 (FIG. 1) and 112 (FIG. 1) to deal separately with phenomena acting over different length scales. Alternatively, depending on the nature of the initial mathematical surface profile model and comparison algorithm used, insertion of the test values and preliminary surface parameters into the initial mathematical surface profile model may be delayed until the comparison block.

Turning to FIG. 4, which illustrates, in block-diagram form, a hardware system incorporating the invention. As indicated therein, the system includes a system bus 400, over which all system components communicate, a mass storage device (such as a hard disk or optical storage unit) 402 as well as a main system memory 404.

The operation of the illustrated system is directed by a central-processing unit ("CPU") 406. The user interacts with the system using a keyboard 408 and a position-sensing device (e.g., a mouse) 410. The output of either device can be used to designate information or select particular areas of a screen display 412 to direct functions to be performed by the system.

The main memory 404 contains a group of modules that control the operation of CPU 406 and its interaction with the other hardware components. An operating system 414 directs the execution of low-level, basic system functions such as memory allocation, file management and operation of mass storage devices 402. At a higher level, an analysis module 416, implemented as a series of stored instructions, directs execution of the primary functions performed by the invention, as discussed below. Instructions defining a user interface 418 allow straightforward interaction over screen display 412. User interface 418 generates words or graphical images on display 412 to prompt action by the user, and accepts user commands from keyboard 408 and/or position-sensing device 410. The main memory 404 also includes one or more database 420, in general containing any of the test or process values of input parameters including input variables, the desired profile, the test surface profile and rough preliminary test values in the plasma model and profile simulator.

It must be understood that although the modules of main memory 404 have been described separately, this is for clarity of presentation only; so long as the system performs all necessary functions, it is immaterial how they are distributed within the system and its programming architecture.

The test surface profile(s) is produced experimentally, as is well known in the art, by subjecting one or more test substrates to a test process(es) in a plasma

reactor and measuring the resulting surface profile using, for example, scanning electron microscopy. The desired and test surface profiles may be supplied to the hardware system in electronic format or as graphic hardcopy, in which case the image(s) is processed by a digitizer 398 before numerical comparison with the
5 approximate prediction. The digitized profile is sent as bitstreams on the bus 400 to a database 420 of the main memory 404. The test surface profile may be stored in the mass storage device 402 as well as in database 420.

As noted above, execution of the key tasks associated with the present
10 invention is directed by analysis module 416, which governs the operation of CPU 406 and controls its interaction with main memory 404 in performing the blocks necessary to provide a final mathematical surface profile model including calibrated optimum test values in the initial surface profile model; and, by further processing based on the final surface profile model and a desired surface profile,
15 to determine process values of one or more input variables governing a plasma process sequence appropriates for creating the desired profile on a process substrate; or, by inserting process values of the input variables into the final mathematical model, to predictively calculate a process surface profile to be created on a process substrate by a plasma process sequence defined by the
20 process values.

In particular, the hardware system depicted in FIG. 3 may be used to implement the calibration procedure illustrated by FIG. 1 as follows. The input

variable test values selected in block 104, the test values of any fixed input parameter, and the test surface profile created in block 114 and, as needed, the desired surface profile and/or process values of interest are provided to the database 420 so that they are available to the analysis module 416. Alternatively, the module 416 may retrieve any of the test values, rough preliminary values and test surface profile data from the mass storage device 402 or user interface 418 in response to a user command. Or, the rough preliminary values may be determined by the module 416, based on the input variable test values, according to a predetermined algorithm.

Turning now to FIG. 1, by executing the plasma modeling and profile simulation of blocks 108 and 112, respectively, the module 416 establishes the initial mathematical surface model predicting the profile created by the test process. In block 116, the module 416 (FIG. 4) accesses the test surface profile and compares it with the initial mathematical surface profile model and evaluates the residual according to some predetermined criterion. If the residual is not sufficiently small, the analysis module 416 uses the results of the comparison to adjust the test values of the plasma model and profile simulator in block 118. The new test values are retained in the database 420 for another iteration of the modeling/simulation and comparison blocks. When the test surface profile and approximate prediction are sufficiently similar, the test values used in that final iteration are stored in the database 420 as the optimum values.

The analysis module uses these optimum values of the input variables for computation of process values, which can be loaded into a plasma reactor for production of a device including the desired profile, or for profile prediction as
5 described above.

It will therefore be seen that the foregoing represents a highly extensible and advantageous approach to plasma processing of semiconductor devices. The terms and expressions employed herein are used as terms of description and not of
10 limitation, and there is no intention, in the use of such terms and expressions, of excluding any equivalents of the features shown and described or portions thereof, but it is recognized that various modifications are possible within the scope of the invention claimed. For example, the various modules of the invention can be implemented on a general-purpose computer using appropriate software
15 instructions, or on a network of computers, or a multiprocessor computer or as hardware circuits, or as mixed hardware-software combinations (wherein, for example, plasma modeling and profile simulation are performed by dedicated hardware components).

20 While embodiments and applications of this invention have been shown and described, it would be apparent to those skilled in the art having the benefit of this disclosure that many more modifications than mentioned above are possible

[illegible]
